Climatic or geologic controls, such as tectonics or glacial drainage, might impose constraints on landscape self-organization resulting in spatial patterns of rivers and valleys which do not obey the typical self-similar relationships found in most landscapes. The goal of this study is to quantify how such geologic constraints express themselves on channel network topology, spatial heterogeneity of drainage patterns, and emergence of preferred scales of landscape dissection. We use as an example a basin located in the Upper Midwestern United States where successive glaciations over the past thousand years have led to a pronounced spatially anisotropic channel network structure which defeats most scaling laws of fluvial landscapes. This is contrasted with another river basin in the North-Central U.S. which has been organized under the absence of major geologic influences and follows a typical self-similar channel network organization. We show how the geologic constraints have imposed a competition for space which is captured in the slope-local drainage density probabilistic structure, in the failure of self-similarity in basin-wide river network topology, and in the length-area scaling relationship being not typical of fluvial landscapes. Via a two-dimensional wavelet analysis and synthesis, we demonstrate the occurrence of a gap in the power spectrum which corresponds to the presence of preferred scales of organization, and characterize them through multi-scale detrending. The developed methodologies can be useful in advancing our geomorphologic understanding of how external controls might manifest themselves in creating a landscape dissection that is outside the norm and how this dissection can be studied objectively for understanding cause and effect.

1. Introduction

Landscape self-organization driven by the movement of water and sediment, and the emergence of river networks that exhibit a hierarchical structure across a range of scales have been the subjects of intensive research over the past decades (e.g., see Rodriguez-Iturbe and Rinaldo, 2001 and references therein). Recently, Zanardo et al. (2013) studied 408 river networks from 50 basins with different geographic location and climate across the United States to assess if the majority of the river networks exhibit self-similarity (SS) in their topological structure. Through a rigorous statistical testing of the Hortonian and Tokunaga self-similarities (see Zanardo et al., 2013 for a detailed representation of these tests), they concluded that 96% of the river networks overwhelmingly exhibited Hortonian Self-Similarity (HSS), while 80% of them followed a topological hierarchical structure that can be characterized successfully by Tokunaga Self-Similarity (TSS). Despite the wealth of studies on landscapes drained by river networks that exhibit HSS, detailed studies of those 20% basins that break the stricter TSS are lacking. The goal of this work is to explore such “outlier basins” which we call “self-dissimilar” and propose methodologies that can probe into their structure in ways that are able to reveal spatially heterogeneous organization and preferential scales of dissection, which then can be related to the underlying controls of, e.g., climate or geology.

Fig. 1a illustrates an example of such basins corresponding to the 43,400 km² Minnesota River Basin (MRB) located in the Upper Midwestern United States. The geologic history of the MRB (Ojakangas, 1982; Nicollet, 1993) reveals that successive glaciations around 100,000–10,000 BP and the draining of glacial Lake Agassiz in 13,400 BP drastically carved this landscape (Clayton and Moran, 1982; Belmont et al., 2011). While glacial lobes draining over most of this basin left behind a flat and lake-punctuated landscape in the central-
eastern part, the western bedrock part was not eroded (Fig. 1b). Instead, repeated glacial cycles covered that bedrock with glacial till deposits and formed the 320 km long, 160 km wide geological feature called Coteau des Prairies (CDP) residing along the South Dakota border and extending to the northwestern part of the MRB. At the edge of the CDP (Fig. 1c,d) there is a pronounced difference in the fluvial dissection compared to the rest of the basin, expressed by the presence of a dense number of steep channels and quasi-periodic ridges and valleys. This high slope region (HSR) includes channels with slope larger than 0.01 m m$^{-1}$ and maximum elevation less than 500 m. A cross-section...
of these almost parallel channels in Fig. 1d reveals that these are not rills, but well-formed channels ranging in depth from 10 to 20 m. The longitudinal profile (Fig. 1e) of the analyzed area shown by the box in Fig. 1b and expanded in Fig. 1c shows a 200 m drop in elevation within a 12 km horizontal distance, resulting in the gradient of 0.017 m m$^{-1}$ (see also Gran et al., 2009).

Fig. 2a,d shows the Digital Elevation Model (DEM) and the drainage pattern of the Headwaters River Basin, one of the 12 major sub-basins of the MRB, encompassing a portion of the CDP with a peculiar river network topology, and Fig. 2b,e shows those of the Upper Bluestone River Basin in West Virginia, U.S., as another example of a geologically-controlled landscape. The Upper Bluestone River Basin is a tributary of the much bigger New River Basin, which experienced ten geologic eras and periods dividing the basin into three major physiographic provinces, that is, Appalachian Plateaus, Ridge and Valley, and the Blue Ridge Provinces (Paybins, 2000). The Ordovician Taconic Orogeny was the first well-known tectonic event which formed a chain of mountains to the north and east of West Virginia, and the next Devonian Acadian Orogeny tectonic event further formed a new set of mountains to the northeast. This strong folding and thrust faulting resulted in the development of long folded ridges which are underlain by sedimentary rocks and separated by relatively flat, broad valleys (Cardwell, 1975).

The above basins are only a few examples of a broader category of geologically-controlled landscapes at which deviation from the universal scaling relationships is recognizable from both the landscape dissection structure and the underlying forming processes. For instance, contrasting relationships were found between specific sediment yield and drainage area across a wide range of spatial scales in various regions of Canada, as compared to the typically observed negative correlation (between specific sediment yield and drainage area), e.g., in the south-eastern United States (e.g., see de Vente et al., 2007 and references therein). These opposing trends have been associated with the activity of rivers that are still responding to large volumes of sediments remobilized during periods of glaciation (e.g., Church and Slaymaker, 1989). In the study of slope-control on the aspect ratio of weakly dissected river basins (~10$^{-5}$ km$^{2}$), Castelltort et al. (2009) also attributed anomalous results obtained from some basins in the Columbia River Basin (46° 0' 0" N, 116° 0' 0" W) to the influence of past tectonics when the North-American plate moved south-west over the Yellowstone Plume.

Although subjected to a different type of control, all the aforementioned basins share communalities of carrying the imprint of external forcing, offering a playground for advancing our geomorphological understanding of cause and effect, studying quantitatively how geologic constrains express themselves on the river network topology, and developing objective methodologies that can explore the spatial heterogeneity and variability of such basins as a function of scale. Addressing these issues constitutes the chief objective of this study. We additionally highlight the morphological differences between self-dissimilar and self-similar landscapes by contrasting the Headwaters River Basin with the 4900 km$^{2}$ Methow River Basin (Fig. 2c,f) located in North-Central Washington, which is known to exhibit a typical self-similar channel network organization (Zanardo et al., 2013) and to have reached a geomorphic stable condition (United States Bureau of Reclamation, 2008).

To address questions of spatial heterogeneity across different scales and quantify the particular scales and locations contributing mostly to the landscape variability, a localized multi-scale analysis framework, such as that provided by wavelets, is needed. Wavelet analysis has attractive properties such as spatial and spectral localization which allow characterization of differences in the shape and orientation of topographic features in either one or two dimensions (e.g., Booth et al.,
branching (a respectively. The linear relationships with coefficients of determination, Fig. 4a show the Horton law of the number of branches, giving the bifurcation ratio of two consecutive branches of order i if we assume it maintains the bifurcation ratio throughout the lower-order branches. However, topologic analysis of this river network reveals that there exists a lower number of streams with orders 2 to 5, but a much larger number of first-order streams (648) than expected. Fig. 3a shows that the vast majority of such first-order streams not only is present in the high slope region (HSR) of the CDP, but also these streams drain almost parallel to each other decreasing the chance to join and create higher order streams, which ultimately results in a smaller bifurcation ratio than expected for typical landscapes.

2. Landscape dissection analysis

2.1. Tests of Hortonian and Tokunaga self-similarity

If a river network is represented by a tree composed of links (stream channels) and nodes (stream junctions), in the Horton-Strahler ordering scheme: (1) external links or sources have order equal to 1; (2) when links of the same order w join, the order of the immediate downstream link is w + 1; and (3) the link directly downstream of two joining links with different orders is labeled with the highest order of the two (Horton, 1945; Strahler, 1957). The order (Ω) of a finite river network is equal to the maximum order of links present in the network. For a Hortonian self-similar river network, Nw / Nw+1 = Rw, where Rw is the so-called bifurcation ratio, and Nw is the number of branches of order w, where branches are defined as connected links of the same order. Other commonly studied Horton laws also apply in terms of the average length and average upstream contributing area of the branches of order w, but are not considered here.

The Tokunaga indexing accounts for the side branching structure of a river network, i.e., if Nj is the number of branches of order j that join a branch of order j, and Ni is the total number of branches of order j, the Tokunaga index Ti is defined as Ti = Ni / Ni. Thus Ti can be interpreted as the average number of branches of order i that join a branch of order j. If τj0 (1 ≤ i ≤ Nj, 1 ≤ i < j ≤ Ω) denotes the number of branches of order i that join the nonterminal nodes of the i-th branch of order j > i, a tree is called self-similar if its side-branching structure is the same for all branches of the same order (i.e., τj,k = τj, 1 ≤ i < j ≤ Ω) and is also independent of the branch order (i.e., τj,j,k = τj,k). The TSS considers not only the number of branches of order w draining into branches of order w + 1, that is, Nw+1 / Nw, but also the transition probability of a branch of order w to drain into a branch of order w + k, implying higher order branching. It was found that the total number of low order side-branches (i.e., N12, N23, N34, N35, N46, N57, N68, which are essentially all the existing transitions in the HSR, forms nearly 60% of the same transitions present within the whole basin. This indicates how the hierarchical progression from one order to another is overwhelmingly violated at the above transitions, probing further examination of the causes of the abundance of lower order side-branching within the HSR. Indeed, steep facies (or knickzones) created by the geologic forcing in this region have maintained large areas of low convergence inhibiting the merging of streams to higher orders and resulting in a large number of low order channels within the HSR. This observation is further investigated in the next section by studying the local drainage density and other geomorphic attributes of the landscape.

2.2. Slope–local drainage density analysis

Drainage density, which is a measure of how dense a landscape is dissected by fluvial channels, has been the focus of several studies aiming to understand how dissection is controlled by factors related to climate and relief (e.g., Tucker and Bras, 1998 and references therein). Since drainage density in its global form (defined as the total length of fluvial channels divided by total drainage area) cannot account for spatial heterogeneities in a landscape, we compute here the local drainage density (LDD), defined as the ratio of the length of a channel to the incremental contributing area draining directly into that channel. Based on this definition, Fig. 4a–d illustrates the color mapping of LDD as well as the channel slope (S) on the river network of the Headwaters and Methow basins.

First, it is observed that although the local slopes in the Headwaters basin are on average smaller than those in the Methow basin (average slope of 0.009 m m−1 vs. 0.129 m m−1, respectively), a reversal is found for LDD values (average LDD of 1.49 km km−2 vs. 1.02 km km−2, respectively). The maximum LDD value in the Headwaters basin (4.98 km km−2) is also twice as large as the maximum LDD value in the Methow basin (2.49 km km−2), implying that LDD does not necessarily increase with the local slope (see Table 1 for other statistics on the channel slope and LDD). This is counterintuitive as one expects steeper slopes to create longer and narrower incremental areas due to less flow convergence; however, the deviation found here can be an indicator of large-scale heterogeneities in the landscape imposed by geologic controls (e.g., Castelltort and Simpson, 2006; Castelltort et al., 2009). Second, higher LDD values in the Headwaters...
basin are concentrated in the HSR which is very steep and dissected by low order channels (up to order 3), while the Methow basin shows a spatially uniform distribution of slope and LDD values. A functional comparison of slope and LDD, as shown in Fig. 4e, further confirms that in the Headwaters river basin high values of LDD and slope fall in the same topographic region related to the HSR, while this is clearly not true in the Methow basin where channels with high LDD do not necessarily correspond to high slopes but span a relatively wide range of slopes. These observations underscore not only the subtle differences between the Headwaters and Methow basins with respect to their landscape organization, but also highlight how the Headwaters basin’s HSR has experienced a completely different dissection mechanism compared to the rest of the basin. Fig. 4f quantifies this by showing the scaling relationship between the channel length and incremental drainage area for all the channels within and outside of the HSR. The high scaling exponent of 0.70 for the HSR affirms the presence of longer streams and narrower contributing areas in this region, demonstrating the particular type of dissection formed in this part of the landscape.

Fig. 3. Topology and tests of self-similarity (SS) for the river networks of the Headwaters and Methow basins. (a) and (b) show the channel network colored by the Horton-Strahler order in the Headwaters and Methow basin, respectively. (c) and (d) depict the Hortonian scaling for the number of branches, confirming the Hortonian self-similarity (HSS) for both river networks. (e) and (f) show the Tokunaga index versus side-branching order, revealing that the stricter Tokunaga self-similarity (TSS) is violated in the Headwaters basin, but not in the Methow basin.
To probe further into the relationship between LDD and local slope and specifically to investigate how this relationship might change in a magnitude–frequency space under the presence of spatial heterogeneity, the joint probabilistic structure of these two attributes is studied. Fig. 5c,d shows the quantile–quantile (Q–Q) plots of LDD and slope for the Headwaters and Methow basins, while Fig. 5a,b shows the marginal probability distributions functions (PDFs). In the Methow basin, the LDD and slope PDFs follow each other up to the 92nd quantile after which the tails of the two distributions diverge as evidenced by their deviation from the line passing through the 25th and 75th quantiles. However, this breaking point (corresponding to \( S^* \) and LDD*) for the Headwaters basin takes place at the 76th quantile, indicating that higher slopes do not necessarily support higher LDD values. The position of all channels with LDD and slope beyond the Q–Q plot’s breakpoint are mapped on the Headwaters and Methow river networks as depicted in Fig. 5e and f, respectively. It is seen that these...
channels are located throughout the Methow basin while they are concentrated within the HSR in the Headwaters basin. Indeed, the western part of the Headwaters landscape has been confined in space creating competition for the developing channels, resulting in the formation of long and fairly parallel low-order channels. Such a preferential dissection and reduced LDD variability at small spatial scales once again is a signature of the strong influence of external forcings, geologic control in this basin, on the landscape organization, leading to deviation from the typical relationships under SS. It is interesting to report that the same analysis performed on the Bluestone River Basin showed a breakpoint of the Q–Q plot of the LDD–Slope at approximately the same 75th quantile. Although we are far from making a general conclusion about the quantile of the occurring breakpoint for self-similar landscapes, it is apparent that this Q–Q plot can serve as an indicator of deviation from SS and the presence of heterogeneity in the spatial organization of a landscape. Our next goal is to quantify spatial scales of preferred dissection for which we need appropriate tools such as localized decomposition to interrogate the landscape locally. This issue is examined in the next section.

3. Landscape multi-scale analysis and preferred scales of organization

Multi-scale filtering of landscapes for isolating features within a desired range of scales can be achieved by spectral analysis via Fourier Transform (FT) or Wavelet Transform (WT). Both the FT and the WT perform a convolution of the landscape topography with a family of functions, that is, the sine and cosine functions for the FT and the wavelet functions for the WT. In spite of the widespread application of the FT to study topographic data (e.g., Ansoult, 1989; Hough, 1989; Cheng et al., 2000; Wörmann et al., 2007; Perron et al., 2008; Orloff et al., 2013), its disadvantages include the lack of spatial localization and the prerequisite for parametric removal of large-scale trends or non-stationarities in the data before the FT can be applied. Instead, the WT is a localized transform in space and frequency and allows for the non-parametric removal of trends by appropriate selection of the mother wavelet (Foufoula-Georgiou and Kumar, 1994; Mallat, 1989a,b).

The WT of a signal \( R(t) \) is defined as

\[
WTf(\lambda, b) = \langle f(t), \psi_{\lambda, b}(t) \rangle = \int_{-\infty}^{+\infty} f(t) \psi_{\lambda, b}(t) dt \tag{1}
\]

where \( \langle \cdot, \cdot \rangle \) denotes the inner product (convolution) of \( f(t) \) with a family of functions \( \psi_{\lambda, b}(t) \) which are the complex conjugates of the wavelet function \( \psi_{\lambda, b}^*(t) \), expressed as

\[
\psi_{\lambda, b}(t) = \frac{1}{\sqrt{\lambda}} \psi \left( \frac{t - b}{\lambda} \right), \quad \lambda > 0 \tag{2}
\]

where \( \lambda \) is the scale and \( b \) is the location parameter controlling the contraction (or dilation) and translation of the mother wavelet \( \psi(t) \), respectively. A wavelet function has zero mean, i.e., \( \int_{-\infty}^{+\infty} \psi(t) dt = 0 \), and higher order moments may also be zero, \( \int_{-\infty}^{+\infty} t^k \psi(t) dt = 0, \ k = 0, ..., N - 1 \), allowing removal of polynomial trends up to degree \( N \).

### 3.1. Quantifying preferred scales of organization

The wavelet power spectrum (WPS) of topography measures how the variance of the topography is distributed across scales. Contrary to the Fourier spectrum, it offers the advantage of non-parametric surface detrending and also minimizing aliases via the space-frequency localization property of wavelets (Mallat, 1989a,b). Here we use the Mexican hat wavelet (which has two zero moments and thus removes polynomial trends of order 2) to compute the continuous WPS. Indeed, the power spectrum (PS) can be computed across continuous fine scales via the Continuous Wavelet Transform (CWT), while the dyadic (i.e., power of two) scales in the orthogonal DWT limits the WPS to some definite discrete scales (depending on the size of the data) making it harder to interpret possible abrupt changes in the distribution of energy across scales. A number of past studies have reported that the topography is typically scale-invariant and the PS obeys a single power-law scaling relationship with frequency \( f \) according to \( PS(f) \propto f^{-\beta} \) (e.g., Pelletier, 1999; Veneziano and Iacobellis, 1999; Gagnon et al., 2006). Since the amplitude and the wavelength of topographic features are related to the PS and \( f \), respectively, the spectral slope \( \beta \) indicates how the height-to-width ratio of landforms varies with scale. In general, the spectral slope of a self-similar topography computed from a two-dimensional spectrum is equal to 3 (i.e., the landforms’ height-to-width ratio is independent of scale), while topographies with constant \( \beta \) other than 3 are categorized as self-affine (e.g., Voss, 1988).

Fig. 6a and b show the WPS of the landscape topographies corresponding to a 70 km² patch in the Headwaters basin’s HSR (Fig. 1c,d) and a 190 km² patch extracted from the Methow basin (marked by the box in Fig. 2c), respectively. The WPS of the patch of Methow gives a single spectral slope equal to 2.2 indicating that the landscape topography is self-affine and obeys the same scaling relationship across a range of scales. However, in the Headwaters’ WPS, there are two different scaling regimes with spectral slopes equal to 4.9 and 2.1, separated by a spectral gap between the scales of 0.3 and 1.5 km. The larger spectral slope above the spectral gap implies that large-scale features (i.e., scales larger than 1.5 km) have larger height-to-width ratios compared to small-scale features. The spectral gap within a range of scales indicates an energy plateau which signifies that these scales contribute more to the overall energy (variance of the topography) as compared to the case where the spectrum maintained a constant slope within the whole range of scales; it indeed documents the existence of regular topographic features and some preferred scales of organization. Such features correspond to mildly convergent (almost parallel) channels in the Headwaters basin’s HSR, and the profile of a cross-section in this region shown in Fig. 1d confirms that the scales corresponding to the spectral gap (0.3 to 1.5 km) pertain to the distance between the quasi-periodic ridges and valleys in the HSR. The emergence of a spectral gap, and the presence of two distinctly different scaling regimes around it, is viewed as a signature of “a structured self-dissimilarity” in such landscapes providing information about specific scales of preferred organization and probing the question of understanding the processes that lead to such organization across scales. Topographies that exhibit a break in their power spectra have been reported before, as for example in Perron et al. (2008), but landscapes that exhibit a spectral gap over a range of scales have not been reported before to the best of our knowledge.
3.2. Characterizing landscape regularity via multi-scale detrending

Although for multi-scale analysis of landscapes the continuous wavelet transform is appropriate, for landscape detrending and reconstruction of local features of interest, a DWT is necessary. The discrete wavelet function can be constructed by discretizing the scale and location parameters (usually in a logarithmic scale) written as

$$\psi(t) = \frac{1}{\sqrt{\lambda_0^n}} \psi\left(t - n b_0 \lambda_0^m\right)$$

(3)

where \(m\) and \(n\) are non-zero integers, \(\lambda_0\) is a fixed value greater than 1, and \(b_0\) is a positive value. The convolution of signal \(f(t)\) with \(\psi_{m,n}(t)\) is called the DWT.

By choosing \(\lambda_0 = 2\) and \(b_0 = 1\) (called dyadic grid discretization), a

---

**Fig. 5.** Probabilistic comparison of the channel slope and local drainage density (LDD) in the Headwaters and Methow basins. (a) and (b) show the channel slope and LDD probability distribution function, respectively. (c) and (d) show the quantile-quantile plots of LDD versus slope for the Headwaters and Methow basins, respectively. In panels (e) and (f), green channels have slope larger than \(S^*\), red channels have LDD larger than \(LDD^*\), and black channels are those having both slope larger than \(S^*\) and LDD larger than \(LDD^*\). Concentration of these channels in the Headwaters’ high slope region (HSR) is apparent, while they are distributed throughout the Methow basin. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
certain class of wavelets \( \psi(t) \) can be constructed such that \( \psi_{m,n}(t) \) are orthogonal to their dilations and translations (i.e., \( \langle \psi_{m,n}(t), \psi_{m,n}(t + s) \rangle = \delta_{m,m} \delta_{n,n} \), where \( \delta_{ij} \) is the Kronecker delta function) and form a complete orthonormal basis for all signals that have finite energy. Such signals \( f(t) \) can then be written as a linear combination of the wavelets \( \psi_{m,n}(t) \), i.e.,

\[
    f(t) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} c_{m,n} \psi_{m,n}(t)
\]

where the weights are the inner products of \( \psi \) with certain properties, called the scaling function, such that \( f(t) \) can also be written as

\[
    f(t) = \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} \varphi_{m,n}(t) \psi_{m,n}(t)
\]

where the first term in the RHS represents the average or approximation of \( f(t) \) at scale \( m_0 \) and the second term captures all the “details” of \( f(t) \) at scales equal and smaller than \( m_0 \). It can be easily shown from the above equation that the following recursive equation results:

\[
    \tilde{f}_{m-1}(t) = \tilde{f}_m(t) + s_m f_m(t)
\]

implying that a signal approximation at scale \( m - 1 \), \( \tilde{f}_{m-1}(t) \), can be written as the sum of the signal approximation at the immediately smaller scale \( m \), \( \tilde{f}_m(t) \), plus its detail at that scale, \( s_m f_m(t) \).

Eq. (6) constitutes the so-called wavelet multi-resolution representation (Mallat, 1989a). Multi-resolution representation allows for detrending a landscape through the inverse DWT by successive elimination of large-scale features from the topography to better characterize the complex hierarchy of topographic features. From here on, a detrended landscape is denoted by \( H_n(t, s) \) and is obtained by setting the approximation coefficients at scale \( m \) equal to zero in the reconstruction operation. Fig. 7 schematically shows the general procedure for the multi-resolution decomposition and detrending of a landscape in two dimensions. To analyze two-dimensional topographic data such as DEMs, two-dimensional orthonormal bases can be constructed by taking the tensor product of the one-dimensional scaling and wavelet bases given above (Mallat, 1989a). If the bandpass center frequency of the chosen mother wavelet is \( f_c \), and the data sampling period (which is the resolution of the DEM) is denoted by \( \Delta \), the physical scale \( L_m \) relating to the scale \( m \) is computed by using the following relationship.

\[
    L_m = \frac{2^m \Delta}{f_c}
\]
Fig. 7. General procedure for the wavelet decomposition and detrending of a landscape. (a) Schematic diagram of the multi-resolution representation of a landscape using two-dimensional discrete wavelet transform (DWT). $A^i$, $D^{2x}$, $D^{2y}$, and $D^{4x}$, $i = 1, \ldots, N$, are the approximation, horizontal detail, vertical detail, and diagonal detail matrices at scale $i$, respectively. (b) Flowchart of the multi-scale detrending of a landscape using two-dimensional DWT. The detrending procedure starts by setting the approximation coefficients at the largest scale to 0. In the next iterations, the detail coefficients from large to smaller scales are successively set to 0, until all the details are removed from the landscape.

Fig. 8. Elevation probability distribution and the variance of detrended landscapes against scale. (a and b) Probability distribution of the detrended landscapes for the patch of Headwaters and Methow basins, respectively. (c and d) Variance of the detrended landscapes, $H_m(t,s)$, against scale, $L_m$. The horizontal axis in these plots gives the largest scale present in $H_m(t,s)$. (e) Image view of the detrended landscape, $H_4(t,s)$, from the patch of Headwaters basin, showing regularity that corresponds to the quasi-periodic ridges and valleys in the Headwaters’ high slope region (HSR).
4. Conclusions

Landsapes possess a hierarchical variability over a wide range of scales: from hillslopes to valleys, and to nested river basins of increasing order. If the physical processes that sculpted a landscape are spatially homogeneous, then it is expected that some kind of order in how this variability changes with scale will be found. In fact, a considerable body of work has centered over the past three decades on quantifying SS in landscape dissection (e.g., see Rodriguez-Iturbe and Rinaldo, 2001). However, if geologically or geomorphologically spatially heterogeneous processes dominated the landscape evolution, one would expect that this heterogeneity will be reflected over some range of scales which would exhibit different spatial organization and variability than other scales. The purpose of this study was to examine landscapes which exhibit spatial heterogeneity in their dissection, and via localized analysis and synthesis identify and quantify scales of prefered organization and relate them to the underlying geologic controls. We call these landscapes “self-dissimilar” and suggest that research is needed to both theoretically characterize these landscapes and to connect their structure to the underlying climatic, tectonic, or geologic mechanisms that have broken the typical symmetries that most landscapes possess. From the analysis presented here, the following conclusions are made:

1) Even in basins which exhibit visually distinct spatially heterogeneous river branching structures, HSS analysis is unable to capture broken symmetries in network topology. However, the stricter TSS analysis can detect the presence of hierarchical irregularities in the branching structure of the river networks.

2) The probabilistic dependence of local slope and LDD, examined via a quantile-quantile analysis, has the potential to quantify spatial heterogeneities in landscape dissection by a disproportional lack of high LDD at high slopes. Such an analysis is easy to perform and can be a first step in detecting spatial heterogeneities in landscape dissection, which then can be explicitly positioned on the landscape to study cause and effect.

3) The presence of a spectral gap (no net decrease in energy with decreasing scale) in WPS can reveal scales at which excess regularity is present, as for example in the quasi-periodic ridges and valleys, in our case.

4) Using appropriate localized multi-scale filters, the structure of these regular features can be quantified via localized multi-scale detrending by successive removal of features from the largest to the smallest scale of interest.

The analysis presented herein highlighted the need to develop formal methods for studying spatially heterogeneous landscapes in order to understand their drainage structure and relate it to the underlying causative mechanisms. A detailed spatial and spectral interrogation of a landscape as presented herein to detect specific scales and relating them to certain terrain features cannot be achieved by only studying the landscape DEM and geomorphometric attributes, e.g., slope, aspect, and curvature, as these do not provide information about the landscape hierarchical structure. Our study is but one example of demonstrating how the joint landscape decomposition and detrending via the two-dimensional DWT allows for identifying, mapping, and correlating the spatial patterns of DEM to particular geologic structures. Other potential applications of such a framework include, but not limited to, automatic extraction of deep-seated landslides (Kalbermatten et al., 2012; Doglioni and Simeone, 2013) and characterizing their morphologic features such as topography, hummocky, and scarp (Booth et al., 2009), separating erosional features from the landform of a volcano as well as retrieving volcanic activity from topography (Gomez, 2012), and investigating the periodicity and spatial pattern of lineaments associated with tectonic faults (Jordan and Schott, 2005).

Acknowledgments

This research was funded by NSF grant EAR-1209402 under the Water Sustainability and Climate Program (WSC): REACH (REsilience under Accelerated CHange) and benefited from collaborations made possible by NSF grants EAR-1242458 (LIFE: Linked Institutions for Future Earth) and EAR-1342944. The second author acknowledges financial support from the National Center for Earth-surace Dynamics 2 (NSF grant EAR-1246761) postdoctoral fellowship. The third author also acknowledges support provided by the Joseph T. and Rose S. Ling endowed chair.
